**Abstract** *Although the majority of concept-learning systems previously designed usually assume that their training sets are well-balanced, this assumption is not necessarily correct. Indeed, there exist many domains for which one class is represented by a large number of examples while the other is represented by only a few. The purpose of this paper is 1) to demonstrate experimentally that, at least in the case of connectionist systems, class imbalances hinder the performance of standard classifiers and 2) to compare the performance of several approaches previously proposed to deal with the problem.*

## 1 Introduction

As the field of machine learning makes a rapid transition from the status of “academic discipline” to that of “applied science”, a myriad of new issues, not previously considered by the machine learning community, is now coming into light. One such issue is the *class imbalance* problem. The class imbalance problem corresponds to domains for which one class is represented by a large number of examples while the other is represented by only a few.<sup>1</sup>

The class imbalance problem is of crucial importance since it is encountered by a large number of domains of great environmental, vital or commercial importance, and was shown,

in certain cases, to cause a significant bottleneck in the performance attainable by standard learning methods which assume a balanced distribution of the classes. For example, the problem occurs and hinders classification in applications as diverse as the detection of oil spills in satellite radar images [5], the detection of fraudulent telephone calls [1] and in-flight helicopter gearbox fault monitoring [2].

To this point, there have only been a few attempts at dealing with the class imbalance problem ([7], [2], [6], [4], [1], [5]); and these attempts were mostly conducted in isolation. In particular, there has not been, to date, any systematic strive to link specific types of imbalances to the degree of inadequacy of standard classifiers. Furthermore, no comparison of the various methods proposed to remedy the problem has yet been performed.

The purpose of this paper is to address these two concerns in an attempt to unify the research conducted on this problem. In a first part, the paper concentrates on finding out what type of imbalance is most damaging for a standard classifier that expects balanced class distributions; and in a second part, several implementations of three categories of methods previously proposed to tackle the problem are tested and compared on the domains of the first part.

The remainder of the paper is divided into four sections. Section 2 is a statement of the specific questions asked in this study. Section 3 describes the part of the study focus-

---

\*I would like to thank Danny Silver and Afzal Upal for their very helpful comments on a draft of this paper.

<sup>1</sup>In this paper, we only consider the case of concept-learning.

ing on what types of class imbalance problems create difficulties for a standard classifier. Section 4 describes the part of the study designed to compare the three categories of approaches previously attempted and considered here, on the problems of section 3. Sections 5 and 6 conclude the paper.

## 2 Questions of Interest

The study presented in this paper can be thought of as a first step in the investigation of the following two questions:

**Question 1:** What types of imbalances hinder the accuracy performance of standard classifiers?

**Question 2:** What approaches for dealing with the class imbalance problem are most appropriate?

These questions are important since their answers may suggest fruitful directions for future research. In particular, they may help researchers focus their inquiry onto the particular type of solution found most promising, given the particular characteristics identified in their application domain.

Question 1 raises the issue of when class imbalances are damaging. While the studies previously mentioned identified specific domains for which an imbalance was shown to hurt the performance of certain standard classifiers, they did not discuss the questions of whether imbalances are always damaging and to what extent different types of imbalances affect classification performances. This paper takes a global stance and answers these questions in the context of the DMLP classifier<sup>2</sup> on a series of artificial domains spanning a large combination of characteristics.

Question 2 considers three categories of approaches previously proposed by independent

researchers for tackling the class imbalance problem<sup>3</sup>:

1. Methods in which the class represented by a small data set gets over-sampled so as to match the size of the other class [6].
2. Methods in which the class represented by the large data set can be down-sized so as to match the size of the other class [4].
3. Methods that mostly ignore one of the two classes, altogether, by using a recognition-based instead of a discrimination-based inductive scheme ([2], [5]).

The quest of this part of the study is aimed at finding out what approaches are most appropriate given certain specific domain conditions. In order to answer this question, each scheme was implemented using closely related methods, namely, various versions of Discrimination-based and Recognition-based MLP networks (DMLP and RMLP<sup>4</sup>), in an attempt to limit the amount of bias that could be introduced by different and unrelated learning paradigms. All the schemes were tested on the artificial domains previously generated to answer Question 1.

Note that although this study is restricted to artificial domains, it could be easily extended to real-world domains. In particular, text classification domains could be good test beds given the imbalanced nature of their data sets, the wide availability of text data and the ease with which concept complexity can be controlled—e.g., by merging several categories of text data together in order to form a super-category.

---

<sup>2</sup>DMLP refers to the standard multi-layer perceptron trained to associate an output value of “1” with instances of the positive class and an output value of “0” with instances of the negative class [8].

---

<sup>3</sup>In this study, we focus on “external” approaches to the problem which do not bring upon any modifications to the classifier. The study of “internal” approaches which bias the classifier in order to deal with class imbalances [7] has been left for future work.

<sup>4</sup>RMLP is discussed in Section 4.1 below and in [2].

### 3 When does a Class Imbalance Matter?

In order to answer Question 1, a series of artificial concept-learning domains was generated that varies along three different dimensions: the degree of *concept complexity*, the *size* of the training set, and the level of *imbalance* between the two classes. The standard classifier system tested on this domain was a simple DMLP system such as the one described in [8]. This section first discusses the domain generation process followed by a report of the results obtained by DMLP on the various domains.

#### 3.1 Domain Generation

For the experiments of this section, 125 domains were created with various combinations of concept complexity, training set size, and degree of imbalance. The generation method used was inspired by Schaffer who designed a similar framework for testing the effect of overfitting avoidance in sparse data sets [9]. However, the two data generation schemes present a number of differences.

In more detail, each of the 125 generated domains is one-dimensional with inputs in the  $[0, 1]$  range associated with one of the two classes (1 or 0). The input range is divided into a number of regular intervals (i.e., intervals of the same size), each associated with a different class value. Contiguous intervals have opposite class values and the degree of concept complexity corresponds to the number of alternating intervals present in the domain. Actual training sets are generated from these backbone models by sampling points at random (using a uniform distribution), from each of the intervals. The number of points sampled from each interval depends on the size of the domain as well as on its degree of imbalance. An example of a backbone model is shown in Figure 1.

Five different complexity levels were considered ( $c = 1..5$ ) where each level,  $c$ , corresponds to a backbone model composed of  $2^c$  regular intervals. For example, the domains generated at

Figure 1: A Backbone Model of Complexity 3

complexity level  $c = 1$  are such that every point whose input is in range  $[0, .5)$  is associated with a class value of 1, while every point whose input is in range  $(.5, 1]$  is associated with a class value of 0; At complexity level  $c = 2$ , points in intervals  $[0, .25)$  and  $(.5, .75)$  are associated with class value 1 while those in intervals  $(.25, .5)$  and  $(.75, 1]$  are associated with class value 0; etc., regardless of the size of the training set and its degree of imbalance.<sup>5</sup>

Five training set sizes were considered ( $s = 1..5$ ) where each size,  $s$ , corresponds to a training set of size  $\text{round}((5000/32) * 2^s)$ . Since this training set size includes all the regular intervals in the domain, each regular interval is, in fact, represented by  $\text{round}(((5000/32) * 2^s)/2^c)$  training points (before the imbalance factor is considered). For example, at a size level of  $s = 1$  and at a complexity level of  $c = 1$  and before any imbalance is taken into consideration, intervals  $[0, .5)$  and  $(.5, 1]$  are each represented by 157 examples; If the size is the same, but the complexity level is  $c = 2$ , then each of intervals  $[0, .25)$ ,  $(.25, .5)$ ,  $(.5, .75)$  and  $(.75, 1]$  contains 78 training examples; etc.

Finally, five levels of class imbalance were also considered ( $i = 1..5$ ) where each level,  $i$ , corresponds to the situation where each sub-interval of class 1 is represented by all the data it is normally entitled to (given  $c$  and  $s$ ), but each sub-interval of class 0 contains only  $1/(32/2^i)$ th (rounded) of all its normally entitled data. This means that each of the sub-intervals of class 0 are represented by  $\text{round}(((5000/32) * 2^s)/2^c)/(32/2^i)$  training examples. For example, for  $c = 1$ ,  $s = 1$ , and  $i = 2$ , interval  $[0, .5)$  is represented by 157 ex-

<sup>5</sup>In this paper, complexity is varied along a single very simple dimension. Other more sophisticated models could be used in order to obtain finer-grained results.

amples and  $(.5, 1]$  is represented by 79; If  $c = 2$ ,  $s = 1$  and  $i = 3$ , then  $[0, .25)$  and  $(.5, .75)$  are each represented by 78 examples while  $(.25, .5)$  and  $(.75, 1]$  are each represented by 20; etc.

In the reported results, the number of testing points representing each sub-interval was kept fixed (at 50). This means that all domains of complexity level  $c = 1$  are tested on 50 positive and 50 negative examples; all domains of complexity level  $c = 2$  are tested on 100 positive and 100 negative examples; etc.

### 3.2 Results for DMLP

The results for DMLP are displayed in Figure 2 which plots the error DMLP obtained for each combination of concept complexity, training set size, and imbalance level. Each plot in Figure 2 represents the plot obtained at a different size. The leftmost plot corresponds to the smallest size ( $s = 1$ ) and progresses until the rightmost plot which corresponds to the largest ( $s = 5$ ). Within each of these plots, each cluster of five bars represent the concept complexity level. The leftmost cluster corresponds to the simplest concept ( $c = 1$ ) and progresses until the rightmost one which corresponds to the most complex ( $c = 5$ ). Within each cluster, finally, each bar corresponds to a particular imbalance level. The leftmost bar corresponds to the most imbalanced level ( $i = 1$ ) and progresses until the rightmost bar which corresponds to the most balanced level ( $i = 5$ , or no imbalance). The height of each bar represents the average percent error rate obtained by DMLP (over five runs on different domains generated from the same backbone model) on the complexity, class size and imbalance level this bar represents. Please note that all graphs indicate a large amount of variance in the results despite the fact that all results were averaged over five different trials. The conclusions derived from these graphs thus reflect general trends rather than specific results. Because the scaling of the different graph is not necessarily the same, lines were drawn at 5, 10, 15, etc. percent error marks in order to facilitate the interpretation of the results.

Because the performance of DMLP depends upon the number of hidden units it uses, we experimented with 2, 4, 8 and 16 hidden units and reported only the results obtained with the optimal network capacity. Other default values were kept fixed (i.e., all the networks were trained by the Levenberg-Marquardt optimization method, the learning rate was set at 0.01; the networks were all trained for a maximum of 300 epochs or until the performance gradient descended below  $10^{-10}$ ; and the threshold for discrimination between the two classes was set at 0.5). This means that the results are reported a-posteriori (after checking all the possible network capacities, the best results are reported). Given the fact that each experiment is re-ran 5 times, it is believed that the a-posteriori view is sufficient, especially since all the systems are tested under the same conditions.

The results indicate several points of interest. First, no matter what the size of the training set is, linearly separable domains (domains of complexity level  $c = 1$ ) do not appear sensitive to any amount of imbalance. Related to this observation is the fact that, as the degree of concept complexity increases (to a point where the problem still obtains an acceptable accuracy when the domain is balanced—i.e., with complexity levels of  $c \leq 4$ , in our particular case), so does the system’s sensitivity to imbalances. Indeed, the gap between the different imbalance levels seems to increase as the degree of concept complexity increases (again, up to  $c = 4$ ) in all the plots of Figure 2.

Finally, it can also be observed that the size of the training set does not appear to be a factor in the size of the error-rate gap between balanced and imbalanced data sets. This suggests that the imbalance problem is a relative problem (i.e., it depends on the proportion of imbalance experienced by the domain) rather than a problem of intrinsic training set size (i.e., it is meaningless to say that a system will perform poorly on a domain that contains only  $n$  negative training examples without specifying the

Figure 2: Experimental Results # 1

size of the positive class<sup>6</sup>).

## 4 A Comparison of Various Strategies

Having identified the domains for which a class imbalance does impair the accuracy of a regular classifier such as DMLP, this section now proposes to compare a few of the methodologies that have been proposed to deal with this problem. First, the various schemes used for this comparison are described, followed by a report on their performance. Rather than comparing specific methods, this study compares various *kinds* of methods. These methods are all implemented in the connectionist paradigm and are closely related so as to minimize differences in performance caused by phenomena other than their particular methodology.

### 4.1 Schemes for Dealing with Class Imbalances

**Re-Sampling** Two re-sampling methods were considered in this category. The first one, *rand\_resamp*, consists of re-sampling the small class at random until it contains as many examples as the other class. The second method, *focused\_resamp*, consists of re-sampling the small class only with data occurring close to the boundaries between the concept and its negation. A factor of  $\alpha = .25$  was chosen to repre-

sent closeness to the boundaries.<sup>7</sup>

**Down-Sizing** Two down-sizing methods, closely related to the re-sampling methods were considered in this category. The first one, *rand\_downsize*, consists of eliminating, at random, elements of the over-sized class until it matches the size of the other class. The second one, *focused\_downsize*, consists of eliminating only elements further away (where, again,  $\alpha = .25$  represents closeness to the boundaries)

**Learning by Recognition** Two methods were, once again, considered in this category. Both of these methods are based on the autoassociation-based classification approach described in [2]. The approach consists of training an autoassociator—a multi-layer perceptron designed to reconstruct its input at the output layer—to learn how to recognize one of the two classes. Once trained, the network will either recognize a testing example as an example of the class it was trained on or reject it as belonging to the class on which it was not trained. This training scheme was used first on the over-represented class of the domain (*over\_recog*) and then on the under-represented class (*under\_recog*). On every domain, the threshold for discriminating between recognized and non-recognized examples was set by comparing the accuracy obtained with

<sup>6</sup>Note, however, that too small a class size is also inherently harmful, but this issue is separate from the one considered here.

<sup>7</sup>This factor means that for interval  $[a, b]$ , data considered close to the boundary are those in  $[a, a + .25 \times (b-a)]$  and  $[a + .75 \times (b-a), b]$ . If no data were found in these intervals (after 500 random trials were attempted), then the data were sampled from the full interval  $[a, b]$  as in the *rand\_resamp* methodology.

100 different threshold values and retaining the one yielding optimal performance.

## 4.2 Results

The results for *rand\_resamp*, *rand\_downsize* and *over\_recog* are reported in Figure 3, while the results for *focused\_resamp*, *focused\_downsize* and *under\_recog* are reported in Figure 4. We only report the results obtained for a single domain size (Size=3).<sup>8</sup>

The results of Figures 3(a), 3(b), 4(a) and 4(b) as compared to those of Figure 2(c) (i.e., DMLP at Size=3) indicate that both re-sampling and down-sizing methods are very effective especially as the concept complexity gets larger. In addition, comparisons of Figures 3(a) and 4(a) as well as 3(b) and 4(b) indicate that there is no clear advantage in using sophisticated re-sampling or down-sizing schemes, at least, in our particular domains.

On the other hand, the performance of *over\_recog* and *under\_recog* is generally not as good as that of *rand\_resamp*, *rand\_downsize*, *focused\_resamp*, and *focused\_downsize*: the overall results obtained by *over\_recog* are less accurate than those of the re-sampling and down-sizing methods. It is only when the complexity of the concept reaches  $c = 5$  (i.e., when, we assume, the problem of recognizing one class is simpler than that of discriminating between two classes) that *over\_recog* becomes slightly more accurate. Furthermore, there does not seem to be any advantage to using *under\_recog* since its results are comparable to those of DMLP used on unaltered imbalanced domains.

## 5 Conclusion

The purpose of this paper was to unify some of the research that has been conducted in isolation on the problem of class imbalance and to guide future research in the area. The paper was concerned with two issues: (1) When

does the class imbalance problem matter? and (2) How do the various categories of methods attempted to solve the problem (and their different realizations) compare?

It concluded that while a standard multi-layer perceptron is not sensitive to the class imbalance problem when applied to linearly separable domains, its sensitivity increases with the complexity of the domain. The size of the training set does not appear to be a factor.

The paper also showed that both over-sampling the minority class and down-sizing the majority class are very effective methods of dealing with the problem. In addition, it showed that using more sophisticated over-sampling or down-sizing methods than a simple uniformly random approach appears unnecessary (at least in the case of feedforward neural networks and simple artificial domains of the type designed for this study).

The recognition-based approach was shown to have the potential to help when used on the majority class. However, it appears less effective than the re-sampling and down-sizing approaches. When applied to the minority class, it does not present any advantages over the discrimination-based approach (DMLP) applied to unaltered imbalanced domains.

## 6 Future Work

There are many directions left to explore in the future. First, it would be useful to test different types of imbalances: so far, only “balanced imbalances” were considered. “Imbalanced imbalances” in which different subclusters of a class have different numbers of examples representing them should also be surveyed.

In order to get a more precise understanding of the different results it would also be useful to report the results in terms of false positives and false negatives or to run ROC Analyses.

A third issue has to do with the type of classifier used. In this study, only feedforward neural networks were considered. It would be worthwhile to check the performance on the problems of Section 3 of other standard classi-

---

<sup>8</sup>Results involving different domain sizes can be found in [3].

Figure 3: Experimental Results # 1

Figure 4: Experimental Results # 2

fiers (e.g., C4.5, Nearest-Neighbours, etc.).

Finally, the use of artificial domains throughout this study may have occulted important issues pertaining to practical problems. It would, thus, be useful to repeat the experiments on real-world domains.
